ABSTRACT

Tourmaline grains extracted from rocks within three ultrahigh-pressure (UHP) metamorphic localities have been subjected to a structurally and chemically detailed analysis to test for any systematic behavior related to temperature and pressure. Dravite from Parigi, Dora Maira, Western Alps (peak *P-T* conditions ~3.7 GPa, 750 °C), has a structural formula of $X(Na_{0.90}Ca_{0.05}K_{0.01}\square_{0.04})Y(Mg_{1.78}Al_{0.99}Fe_{0.12}Ti_{0.03}\square_{0.08})Z(Al_{5.10}Mg_{0.90})(BO_3)_3T(Si_{6.00}O_{18})V(OH)_3W[(OH)_{0.72}F_{0.28}]$. Dravite from Lago di Cignana, Western Alps, Italy (~2.7–2.9 GPa, 600–630 °C), has a formula of $X(Na_{0.84}Ca_{0.09}K_{0.01}\square_{0.06})Y(Mg_{1.64}Al_{0.79}Fe_{0.48}Mn_{0.06}Ti_{0.02}Ni_{0.02}Zn_{0.01})Z(Al_{5.00}Mg_{1.00})(BO_3)_3T(Si_{5.98}Al_{0.02})O_{18}V(OH)_3W[(OH)_{0.65}F_{0.35}]$. “Oxy-schorl” from the Saxonian Erzgebirge, Germany (≥ 4.5 GPa, 1000 °C), most likely formed during exhumation at >2.9 GPa, 870 °C, has a formula of $X(Na_{0.86}Ca_{0.02}K_{0.02}\square_{0.10})Y(Al_{1.63}Fe_{1.23}Ti_{0.11}Mg_{0.03}Zn_{0.01})Z(Al_{5.05}Mg_{0.95})(BO_3)_3T(Si_{5.96}Al_{0.04})O_{18}V(OH)_3W[O_{0.81}F_{0.10}(OH)_{0.09}]$. There is no structural evidence for significant substitution of ¹⁴Si by ¹⁴Al or ¹⁴B in the UHP tourmaline (<T-O> distances ~1.620 Å), even in high-temperature tourmaline from the Erzgebirge. This is in contrast to high-*T*-low-*P* tourmaline, which typically has significant amounts of ¹⁴Al. There is an excellent positive correlation ($r^2 = 1.00$) between total ¹⁶Al (i.e., ^YAl + ^ZAl) and the determined temperature conditions of tourmaline formation from the different localities. Additionally, there is a negative correlation ($r^2 = 0.97$) between F content and the temperature conditions of UHP tourmaline formation and between F and ^YAl content ($r^2 = 1.00$) that is best explained by the exchange vector ^YAlO(R²⁺F)₋₁. This is consistent with the W site (occupied either by F, O, or OH), being part of the YO₆-polyhedron. Hence, the observed Al-Mg disorder between the Y and Z sites is possibly indirectly dependent on the crystallization temperature.

Keywords: Tourmaline, ultrahigh pressure, Saxonian Erzgebirge, Western Alps, Dora Maira, Lago di Cignana

INTRODUCTION AND PREVIOUS WORK

Tourmaline can be formed in different geochemical environments that have undergone magmatic, metasomatic, diagenetic, or metamorphic processes (Henry and Guidotti 1985; Deer et al. 1992; Henry and Dutrow 1992, 1996; Slack 1996; Dutrow et al. 1999; Henry et al. 1999, 2008; Bernardelli et al. 2000; Kawakami 2001; Sengupta et al. 2005; van den Bleeken et al. 2007; Ertl et al. 2008b; Trumbull et al. 2008; Marschall et al. 2009). The general chemical formula of the tourmaline-group minerals is given as $XY_3Z_6[T_6O_{18}](BO_3)_3V_3W$ by Hawthorne and Henry (1999). The X site is usually occupied by Na, Ca, and rarely by K, but can also be vacant. Fe²⁺, Fe³⁺, Mn²⁺, Mg, Li, Cu, Ti⁴⁺, V³⁺, and Cr³⁺ typically occupy the Y site, which is often also characterized by significant amounts (>5% of the site occupancy) of Al. The Z site is usually occupied by Al, but in some cases, contains significant amounts of Mg, Fe³⁺, and, more rarely, V³⁺ and Cr³⁺. The replace-

ment of Al by Mg at the Z site was described by Grice and Ercit (1993), Hawthorne et al. (1993), Bloodaxe et al. (1999), Ertl et al. (2003a, 2008a), Bosi and Lucchesi (2004), Bosi et al. (2004), and Marschall et al. (2004). The T site is usually occupied by Si, but can also incorporate significant amounts of Al (Foit and Rosenberg 1979; MacDonald and Hawthorne 1995) and B (Ertl et al. 1997, 2008b, and references therein).

Tourmaline compositions in metamorphic rocks are strongly related to the local bulk composition and mineral assemblages, but there are some general trends that are apparently a function of metamorphic grade. Based on a survey of natural tourmaline data, Henry and Dutrow (1996) suggested that, at increasing metamorphic grade, there is an increase in tetrahedral Al via the $Al_2(R^{2+}Si)_{-1}$ exchange vector, an increase in F contents at the W site, and a decrease of X-site vacancies via the $X\square Al(NaR^{2+})_{-1}$ exchange vector (where R²⁺ = Fe²⁺, Mn²⁺, Mg). In contrast, the experimental study of van Goerne et al. (2001) suggested that for a fixed Na content in the fluid phase, the latter exchange

* E-mail: andreas.ertl@al.net

vector increases with temperature. A further trend observed in natural tourmaline is an increase in Ti as a function of increasing temperature (Thomson 2006). Perhaps the most distinctive temperature-sensitive tourmaline compositional feature is its compositional polarity (sector zoning) such that tourmaline develops significantly different compositions at the opposite poles of the *c*-axis of the tourmaline (Henry and Dutrow 1996; van Hinsberg and Schumacher 2007; van Hinsberg and Marschall 2007). The compositional polarity decreases as a function of temperature and disappears at medium grades of metamorphism and has been suggested as a geothermometer (Henry and Dutrow 1996; van Hinsberg and Schumacher 2007).

TOURMALINE STABILITY

Tourmaline is stable over a wide pressure-temperature (*P-T*) interval (Marschall et al. 2009, and references therein). It ranges from diagenetic/epigenetic through high-grade metamorphic conditions and up to magmatic conditions (e.g., ~150–850 °C at ~0.1–0.4 GPa; Robbins and Yoder 1962; Manning and Pichavant 1983). The stability of dravite was established in experiments by Werding and Schreyer (2002) to lie between pressures of 3–5 GPa and temperatures >950 °C (Fig. 1). The breakdown of dravite to different Al-Mg phases occurs at pressures as high as 6–8 GPa (Krosse 1995). In the presence of coesite, natural tourmaline breaks down at pressures exceeding 4 GPa in the temperature range of 800–850 °C and at 4.5–5 GPa at lower temperatures of about 700 °C (Fig. 1) (Ota et al. 2008).

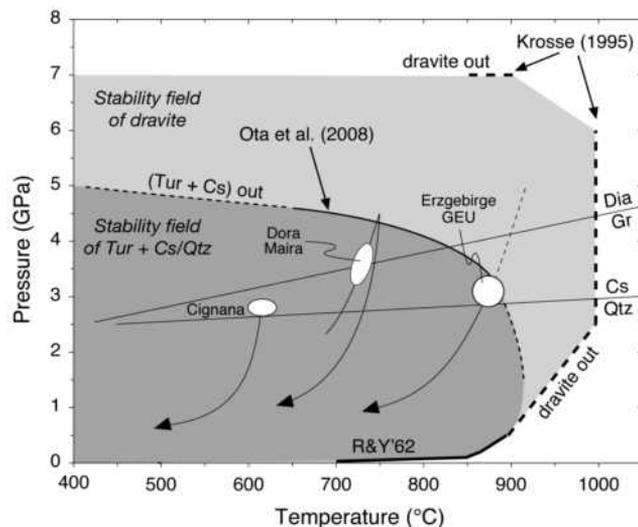

FIGURE 1. *P-T* diagram showing: (1) the experimentally determined stability field of dravite tourmaline (light gray) (Robbins and Yoder 1962; Krosse 1995; Werding and Schreyer 2002) and tourmaline + coesite/quartz (dark gray) (Ota et al. 2008), and (2) peak metamorphic conditions of the different tourmaline-bearing UHP rocks investigated (white ellipses): Diamond- and coesite-bearing gneisses from the gneiss-eclogite unit (GEU) of the Saxonian Erzgebirge, Germany (Schmädicke and Müller 2000; Massonne 2003; Massonne et al. 2007); coesite-pyrope-kyanite quartzite from the Dora Maira massif, Western Alps, Italy (Schreyer 1985; Schertl et al. 1991); coesite-bearing metasediments from Lago di Cignana, Western Alps, Italy (Reinecke 1991, 1998; Bebout and Nakamura 2003). Quartz-coesite and graphite-diamond equilibria after Bohlen and Boettcher (1982) and Bundy (1980), respectively.

REGIONAL GEOLOGY OF THE ULTRAHIGH-PRESSURE (UHP) MASSIFS AND SAMPLE CHARACTERISTICS

In the present study, three different natural tourmaline samples were investigated, all of which formed under ultrahigh-pressure (UHP) metamorphic conditions. One tourmaline sample studied (dravite, no. 15597) comes from a pyrope quartzite from Parigi, Dora Maira Massif, Western Alps, Italy (Chopin 1984). Peak metamorphic conditions were estimated at ~3.5 GPa and 750 °C (Chopin 1984; Schertl et al. 1991; Compagnoni 2003), or possibly at higher pressures within the diamond stability field (Hermann 2003). Quartz pseudomorphs after coesite and tourmaline grains are present as inclusions within pure pyrope (Fig. 2a). According to Schreyer (1985), who investigated the same sample, pyrope replaced a preexisting fabric of oriented tourmaline crystals leading to a poikiloblastic texture (Schreyer 1985, their Fig. 14). Several similarly oriented inclusions of dravite in pyrope were taken as evidence for the growth of pyrope and kyanite at the expense of tourmaline (Schreyer 1985; Schertl et al. 1991). Experimental work by Hermann (2003) revealed that peak conditions of the pyrope quartzite were 4.5 GPa and 750 °C. Interestingly, these conditions are very similar to where the reaction $Tur + Cs = Grt + Cpx + Ky + fluid$ was located experimentally (Ota et al. 2008) (most mineral abbreviations after Kretz 1983). This suggests that the tourmaline in the Dora Maira pyrope quartzite survived diamond facies conditions as monomineralic inclusions in garnet and kyanite, but was decomposed to garnet + kyanite + fluid where in contact with coesite. The Mg-rich quartzites are interpreted as strongly metasomatized equivalents of the surrounding granitic gneisses (Schertl and Schreyer 2008). Hence, the Dora-Maira dravite may have formed during the same metasomatic event. The quartz-bearing (former coesite; Fig. 2a) assemblage confirms that the host pyrope formed as a result of the reaction $talc + kyanite = pyrope + coesite$ (second pyrope-forming reaction; Schertl et al. 1991) near peak metamorphic conditions. Thus, the host pyrope is not a “large pyrope” that may exceed 15 cm in diameter (larger pyrope grains formed along the prograde *P-T* path due to the first pyrope forming reaction $chlorite + kyanite + talc = pyrope$; Schertl et al. 1991) as suggested by Schreyer (1985) in his first exploratory study of this sample.

The second location of UHP rocks from which Mg-rich tourmaline was studied is near Lago di Cignana in the Western Alps (Reinecke 1991, 1998; Bebout and Nakamura 2003). The sample is a metasedimentary piemontite- and talc-bearing garnet-phengite-coesite-schist; *P-T* conditions have been estimated as ~2.7–2.9 GPa and ~600–630 °C (Reinecke 1991, 1998). Reinecke (1991) described inclusions of relict coesite, hematite, rutile, and braunite in tourmaline grains from this locality.

A third UHP tourmaline-bearing locality is located in the Erzgebirge at the northwestern margin of the Bohemian Massif, which is part of the Devonian-Carboniferous metamorphic basement of the Mid-European Variscides exposed in Saxony and the northern Czech Republic. The region is characterized by a stack of five tectono-metamorphic units, each with distinct *P-T* histories (Willner et al. 1997; Rötzler et al. 1998). The investigated sample (R6b) is from the diamond- and coesite-bearing gneiss-eclogite unit (GEU); *P-T* estimates of the eclogite revealed

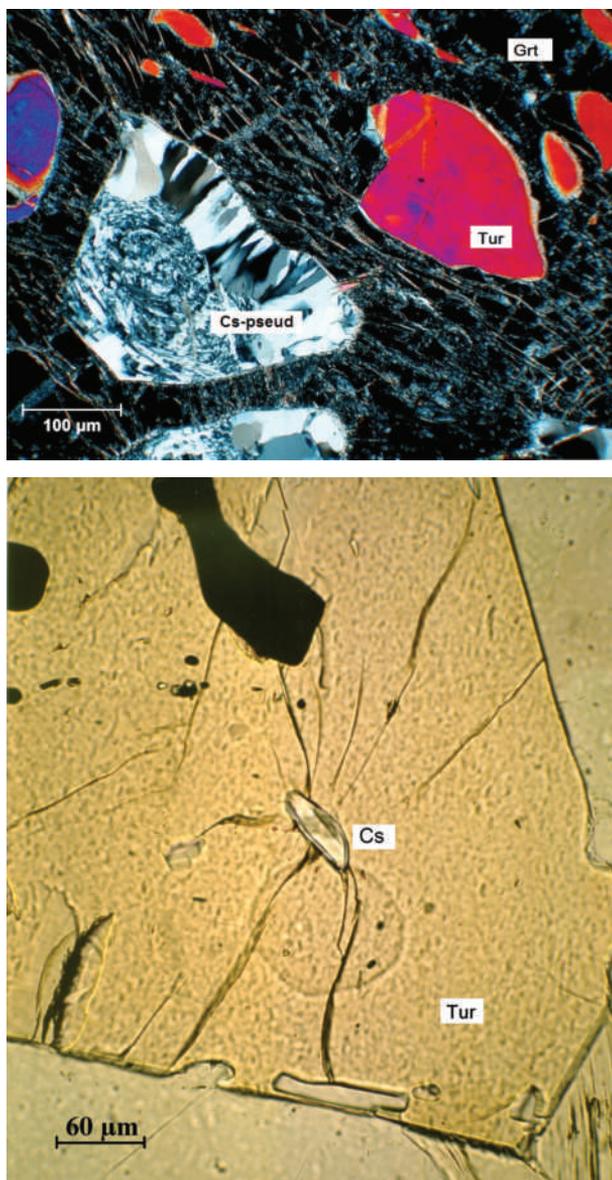

FIGURE 2. (a) Quartz-pseudomorph after coesite (Cs-pseud) and tourmaline (Tur) inclusions in pyrope from Dora Maira, Western Alps, Italy. (b) Relic coesite inclusion (confirmed by Raman spectroscopy; Reinecke 1991) in a euhedral tourmaline crystal from Lago di Cignana, Western Alps, Italy.

conditions of >2.9 GPa at 870 °C (Schmädicke and Müller 2000), but the occurrence of diamond in the felsic gneisses requires pressures in excess of 4 GPa (Massonne 2003; Massonne et al. 2007). Peak metamorphic conditions may have been even higher (8 GPa at >1050 °C; Massonne 2003). The sample was collected as a loose decimeter-sized block from a small creek 5 km ENE of the Saidenbach reservoir, Forchheim, Pockau, Erzgebirge, Saxony, Germany. It is a felsic, medium-grained, granulite-facies mylonite displaying strongly elongated quartz and feldspar with black tourmaline porphyroclasts and minor garnet. Short, prismatic tourmaline crystals are up to 3 mm in length. In thin section (cut perpendicular to the *c*-axis), the tourmaline crystals show three distinct color zones separated by diffuse boundaries:

a blue core, a brownish mantle, and a greenish-gray anhedral rim, the latter of which is intimately intergrown with quartz, feldspar, and phengite in the matrix. Marschall et al. (2009) noted coesite and kyanite inclusions in the mantle zone of tourmaline from Erzgebirge (in sample R6b). A fourth tourmaline sample was available from an UHP gneiss from the Kokchetav Massif, Kazakhstan (Dobretsov et al. 1995), but was not considered because its development under UHP conditions has been questioned (Marschall et al. 2009).

EXPERIMENTAL DETAILS

Sample selection and preparation

Reddish tourmaline crystals were hand picked under the microscope from a crushed piece (~ 5 cm) of the piemontite- and talc-bearing garnet-phengite-coesite-schist (investigated by Reinecke 1998) from Lago di Cignana. After optical inspection, the clearest fragment (sample Laci; $\sim 0.15 \times 0.20 \times 0.24$ mm) was used for single-crystal structure refinements and subsequently for chemical analyses. Similar tourmaline grains from this locality contain coesite inclusions (Reinecke 1991; see also Fig. 2b). The tourmaline fragment from the Dora Maira locality (sample Domai; $0.12 \times 0.15 \times 0.25$ mm) was extracted from a thin section, where it forms anhedral inclusions in a relatively small pyrope crystal (~ 1 cm) (see Schreyer 1985, Fig. 14 therein). The host pyrope of this tourmaline inclusion also contains quartz pseudomorphs after coesite (Fig. 2a). The fragment from Erzgebirge (sample R6b; $0.15 \times 0.22 \times 0.22$ mm) was broken off from the coesite-bearing mantle (Marschall et al. 2009) of a macroscopically black tourmaline crystal. For electron microprobe analyses (EMPA), samples were embedded in araldite epoxy, and flat polished sample mounts were produced.

All UHP tourmaline crystals investigated contain inclusions, which were identified by Raman spectroscopy (data not presented here) and electron microprobe analysis (EMPA). In the sample from Dora Maira a phengite inclusion (~ 2 μ m in diameter) was observed. In the tourmaline from Lago di Cignana, talc (~ 12 μ m in length), zircon (a crystal with ~ 3 μ m in diameter), and a mineral of the epidote group (~ 15 μ m in diameter) with the composition $(\text{Ca}_{1.75}\text{Mn}_{0.25})(\text{Al}_{2.02}\text{Mn}_{0.49}\text{Fe}_{0.49}^{3+})(\text{SiO}_4)(\text{Si}_2\text{O}_7)(\text{O},\text{OH})_2$ were identified. This epidote-group mineral belongs to the piemontite-epidote series with a sursassite component of ~ 13 mol% (similar to the chemical data of piemontite from the matrix of the rock as described by Reinecke 1991). A kyanite inclusion (~ 3 μ m in length) was observed the tourmaline sample from Erzgebirge.

Crystal structure refinement

Tourmaline samples were examined on a Kappa APEX II CCD X-ray single-crystal diffractometer from Bruker AXS equipped with a monochromator optics collimator, graphite-monochromatic $\text{MoK}\alpha$ radiation (Universität Wien). Data were collected at room temperature with sixfold redundancy (up to 80 2θ), and integrated and corrected for Lorentz and polarization factors (Bruker 2001). Absorption correction by evaluation of multiple scans was applied. The structure was refined with SHELXL-97 (Sheldrick 1997) using scattering factors for neutral atoms and a tourmaline starting model from Ertl et al. (2006). Table 1 provides crystal data and details of the structure refinement. Table 2 provides atomic parameters (anisotropic displacement parameters are available upon request or from the MSA American Mineralogist Crystal Structure Database, http://www.minsocam.org/MSA/Crystal_Database.html), and Table 3 provides selected interatomic distances. The H atom bonded to the O3 atom was located from a difference-Fourier map and subsequently refined. Refinement was performed with anisotropic thermal parameters for all non-hydrogen atoms. Site occupancies were refined according to well-known characteristics of the tourmaline structure (Na was refined at the X site; Mg and Fe were refined at the Y site; for other details see Table 2; the correlation coefficients do not show significant correlations in the refinement, e.g., between site occupancy and overall scale factor). The refinement converged at $R1(F)$ values of 1.3–2.0%.

Electron microprobe analyses

The three single crystals that were used for the crystal-structure determination were subsequently analyzed with a CAMECA SX-100 electron microprobe at the Department of Lithospheric Research, Geozentrum, Universität Wien, Austria, equipped with four wavelength-dispersive spectrometers (Table 4).

TABLE 1. Crystallographic data and refinement details for UHP tourmaline samples

Sample	R6b	Domai	Laci

Notes: R6b = Erzgebirge; Domai = Dora Maira; Laci = Lago di Cignana. Definition for *U*_{eq} see Fischer and Tillmanns (1988).

The following (natural and synthetic) standards and X-ray lines for calibration were used: albite (NaKα), olivine (MgKα, SiKα, FeKα), almandine (AlKα), rutile (TiKα), orthoclase (KKα), wollastonite (CaKα), spessartine (MnKα), gahnite (ZnKα), NiO (NiKα), and apatite-(CaF) (FKα). Matrix corrections were performed using the PAP correction procedure provided in the CAMECA's latest PeakSight version 4.0 software. An accelerating voltage of 20 keV and a beam current of 20 nA were used for all elements except for F (10 keV, 20 nA). The method of peak to background ratio with counting time 20 s on peak position and 10 s on each background position were used; the beam was defocused to 5 μm in diameter. Under the conditions described, analytical errors are ±2% relative for major elements and ±5% relative for minor elements as estimated from the

reproducibility observed in multiple measurements. All investigated tourmaline fragments were very homogeneous as indicated by low standard deviations of multiple analyses on single crystals (Table 4).

RESULTS

Crystal structures

The general structural formula of tourmaline is given by Hawthorne and Henry (1999) as XY₃Z₆(BO₃)₃(T₆O₁₈)V₃W, where the V and W sites are anion sites. In the following subsections,

we discuss the occupancy of the different sites of the studied tourmalines samples.

X-site occupancy. In all samples, the X site is occupied mainly by Na (0.84–0.90 apfu) by small amounts of Ca (0.02–0.09 apfu), and by minor amounts of K (≤ 0.02 apfu). X-site vacancies are between 0.04 and 0.10 apfu (Table 4).

Y-site occupancy. The Y site of the samples from Dora Maira and Lago di Cignana is predominantly occupied by Mg, but also contains significant amounts of ^YAl. Only the sample from Erzgebirge contains appreciable amounts of Al (~1.6 apfu) at the Y site, as indicated by the relatively short <Y-O> distance of 2.010 Å (Table 3). The samples from Dora Maira and Lago di Cignana have larger <Y-O> distances with 2.023–2.027 Å indicative of significant amounts of (Mg+Fe²⁺) at the Y site (Table 3). The respective amounts of divalent iron at the Y sites (0.12–1.23 apfu) of the samples investigated are given in Table 4. Although no Mössbauer spectroscopy was performed, a significant amount of Fe³⁺ in these samples is not likely; the color of tourmaline from Dora Maira (very pale brown) and from the mantle zone of Erzgebirge tourmaline (deep brown in thick section) may be explained by intervalence charge transfer of Fe²⁺-Ti⁴⁺ (Rossman 2008). Only the Lago di Cignana sample contains a significant amount of Mn²⁺ (0.06 apfu). This sample may also contain some Mn³⁺, as indicated by the reddish color (Reinitz and Rossman 1988; Ertl et al. 2003b). All samples show small amounts of Ti⁴⁺ (0.02–0.11 apfu). The Lago di Cignana and Erzgebirge samples show minor amounts of Zn (ZnO: 0.06–0.09 wt%; Table 4); the tourmaline from Lago di Cignana is characterized by significant amounts of Ni (NiO: 0.15 wt%; Table 4), which is not surprising because the associated minerals (phlogopite and clinocllore) from the oceanic metasediments also contain significant Ni (0.07–0.18 wt% NiO; Reinecke 1991). Nickel content is probably derived

Notes: R6b = Erzgebirge; Domai = Dora Maira; Laci = Lago di Cignana. Average of 6 EMP analyses for R6b, 8 EMP analyses for Domai, and 15 EMP analyses for Laci. (1) B₂O₃ calculated as B = 3.00 apfu (see text). (2) H₂O content was calculated as OH+F = 4 pfu, except for sample R6b. Total Mn and Fe calculated as MnO and FeO. Chlorine was below the detection limit in all samples. A component was not considered significant unless its value exceeds the uncertainty. b.d. = below detection limit.

* H₂O SIMS data from Marschall et al. (2009).

from serpentinites associated with the metasediments.

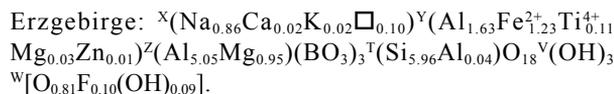

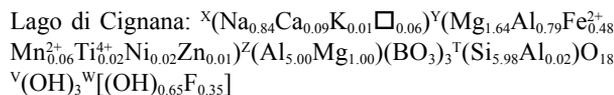

Z-site occupancy. Because of the enlarged <Z-O> bond-length distances relative to tourmaline with only Al at the Z site having <Z-O> distances of 1.906 ± 0.004 Å (Donnay and Barton 1972; Burns et al. 1994; Hughes et al. 2000; Ertl et al. 2003b, 2005, 2006, 2008b), some Al must be substituted by cations with larger ionic radii. Releasing the Z-site occupancy of the structure refinements did not give evidence for a substitution of Al by Fe³⁺ because the refined occupancy (within a 3σ error) shows only Al (and Mg) at the Z site. However, we cannot exclude that small amounts of Fe³⁺ occupy the Z site. Considering the results of crystal-chemical investigations on the schorl-dravite series by Bloodaxe et al. (1999) and Bosi and Lucchesi (2004) and based on our results with <Z-O> distances (1.926–1.929 Å; Table 3), 0.9–1.0 apfu Mg was assigned to occupy the Z site of all investigated samples.

T-site occupancy. Boron was not measured directly and there is no compelling evidence to suggest substitution of Si by B (within a 3σ error) on the T site. The <T-O> distances (~1.620 Å; Table 3) derived for all three studied samples, do not indicate

any significant (>2% site occupancy) substitution of Si by Al or B (Foit and Rosenberg 1979; MacDonald and Hawthorne 1995; Ertl et al. 1997, 2001, 2005, 2006, 2008b). The very small amounts of Al (≤ 0.04 apfu), which were assigned to the T site, may be the result of uncertainty in the chemical analyses or normalization procedures (Table 4), and are not verified by single-crystal X-ray data.

V-site and W-site occupation. Ertl et al. (2002) showed that the bond-angle distortion (σ_{oct}^2) of the ZO_6 octahedron in a tourmaline is largely a function of the <Y-O> distance of the respective tourmaline, although the V-site occupant also affects that distortion. The covariance r , of <Y-O> and σ_{oct}^2 of the ZO_6 octahedron is -0.99 for all investigated tourmaline of Ertl et al. (2002) and Hughes et al. (2004) that are occupied by 3 (OH) groups. The investigated UHP tourmaline samples lie on the V site = 3 (OH) line (see Fig. 3 of Ertl et al. 2002). It is, however, only possible to get a semi-quantitative estimate of the OH content of the O3 site using this relationship. Hence, we assume that the V site in all investigated samples is filled by ~ 3.0 (OH), which is in contrast to buergerite and “oxy-rossmanite,” containing significant amounts of oxygen at this site (Dyar et al. 1998; Ertl et al. 2005). The W site of the investigated tourmaline samples contains low to moderate amounts of F (0.10–0.35 apfu; Table 4). H_2O data, obtained from SIMS analysis, are available for tourmaline from Erzgebirge (sample R6b) from the same hand specimen (Marschall et al. 2009). Therefore, the complete W-site occupancy is estimated to be $\sim [\text{O}_{0.8}\text{F}_{0.1}(\text{OH})_{0.1}]$. The other two samples from Dora Maira and Lago di Cignana exhibit higher F contents, hence the OH content was calculated as $4 - \text{F} = \text{OH}$. With this assumption the calculated H_2O contents result in analytical total sums very close to 100% and are an indication that these values are a good approximation to the actual OH contents.

Because the <T-O> distance is ~ 1.620 Å for all samples (Table 3), which is a typical bond-length for tourmaline where the T site is almost completely occupied by Si (MacDonald and Hawthorne 1995; Bloodaxe et al. 1999; Ertl et al. 2001; Bosi and Lucchesi 2004, average value for all samples with $\text{Si} \geq 5.95$ apfu), the following structural formulae were calculated by assuming $\text{B} = 3$ apfu and on the basis of $(\text{O}, \text{OH}, \text{F}) = 31$ (Table 4):

DISCUSSION

There is a very good positive correlation ($r^2 = 0.99$) between the average charge of the X-site occupants and the F content of the investigated UHP tourmaline samples (Fig. 3). A similar correlation was described for tourmaline of the “fluor-elbaite”-rossmanite solid solution (Ertl et al. 2009). Dutrow and Henry

(2000) found a strong negative correlation between the X-site vacancy and the F content in all generations of magmatic to hydrothermal tourmaline from the Cruzeiro Mine, Minas Gerais, Brazil. Henry (2005) evaluated ~ 600 chemical analyses of different tourmaline varieties in which those with more than 0.5 X-site vacancies had little to no F present. Both relations, using the X-site vacancies or using the average charge of the X-site occupants, are very similar, but the latter approach might be more advantageous. This has been suggested by Ertl et al. (2009), who found that there is a better correlation between the F content and average charge of the X-site occupants than between F and the X-site vacancies.

Henry and Dutrow (1996) pointed out that, in metamorphic tourmaline from pelitic and quartzitic protoliths, the X-site vacancies decrease from 0.6 ± 0.2 to 0.30 ± 0.05 as temperature increases from 200 to 650 °C with further decrease to 0.05 ± 0.05 above 750 °C. In the UHP tourmaline samples, the X-site charges exhibit a negative correlation with temperature of tourmaline formation ($r^2 = 0.92$; Fig. 4). A possible explanation might be a different trend (no increasing ^{141}Al by increasing temperature) of the T-site occupation in UHP tourmaline relative to low-medium pressure tourmaline. Whereas Henry and Dutrow (1996) found that tourmaline of metapelites and metaquartzites that did not exceed metamorphic temperatures of 450 °C contain little or no ^{141}Al , in high-*T* rocks (with $T > 750$ °C), ^{141}Al progressively increases up to an average of 0.25 apfu. In the investigated UHP tourmaline samples that crystallized at temperatures up to ~ 870 °C, there are no indications for significant amounts of ^{141}Al present; a substitution of Si by Al would increase the size of the tetrahedron. At UHP conditions, it is likely that this replacement does not occur, even at relatively high temperatures. Because F is coupled with the average charge of the X-site occupants (Fig. 3), the F content of the UHP tourmaline shows a good nega-

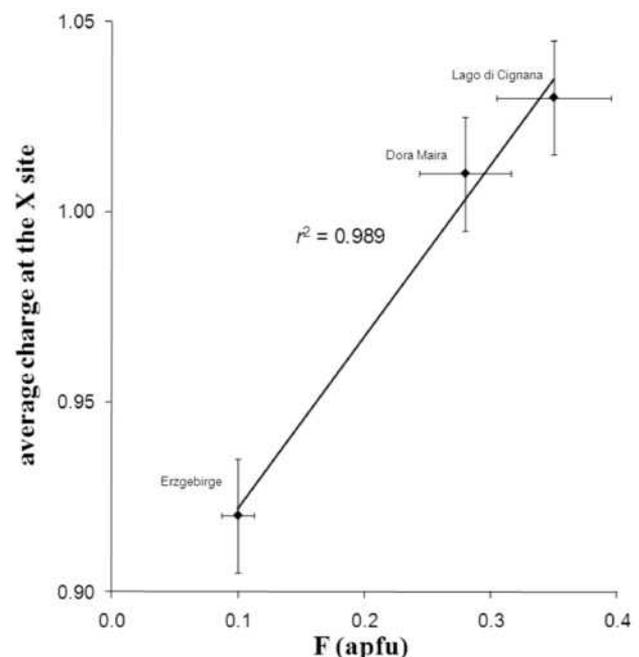

FIGURE 3. Relationship between the F content (Table 4) and average charge at the X site. Bars = average standard deviation ($\pm 1\sigma$).

tive correlation ($r^2 = 0.97$) with the temperature of tourmaline formation (Fig. 5).

Interestingly, a very good correlation ($r^2 = 1.00$; Fig. 6) exists between the average charge of the X-site occupants and $\langle Y-O \rangle$ distances (Table 3). The correlation can only be explained by increased ${}^Y\text{Al}^{3+}$ content as $\langle Y-O \rangle$ distances decrease. This is essentially charge-balanced by decreasing local charge at the X site. Another excellent negative correlation was found between the F content and the ${}^Y\text{Al}^{3+}$ content ($r^2 = 1.00$; Fig. 7). This correlation could be explained with the exchange vector ${}^Y\text{AlO}(\text{R}^{2+}\text{F})_{-1}$. This is consistent with the W site (occupied either by F, O, or

OH), being part of the YO_6 -polyhedron, and its influence on the observed Al-Mg disorder between the Y and Z sites. There is also a strong negative correlation ($r^2 = 0.94$) between the $\langle Y-O \rangle$ distance and the temperature conditions of tourmaline formation (Fig. 8). This correlation suggests an increase in ${}^Y\text{Al}$ content with increasing temperature. Hence, the observed Al-Mg disorder between the Y and Z sites is possibly indirectly dependent on the crystallization temperature. It is interesting to note that the black-colored, Fe-rich, and Mg-bearing tourmaline from Erzgebirge with the formula ${}^X(\text{Na}_{0.86}\text{Ca}_{0.02}\text{K}_{0.02}\square_{0.10}){}^Y(\text{Al}_{1.63}\text{Fe}_{1.23}\text{Ti}_{0.11}\text{Mg}_{0.03}\text{Zn}_{0.01}){}^Z(\text{Al}_{5.05}\text{Mg}_{0.95})(\text{BO}_3)_3{}^T(\text{Si}_{5.96}\text{Al}_{0.04})\text{O}_{18}{}^V(\text{OH})_3$

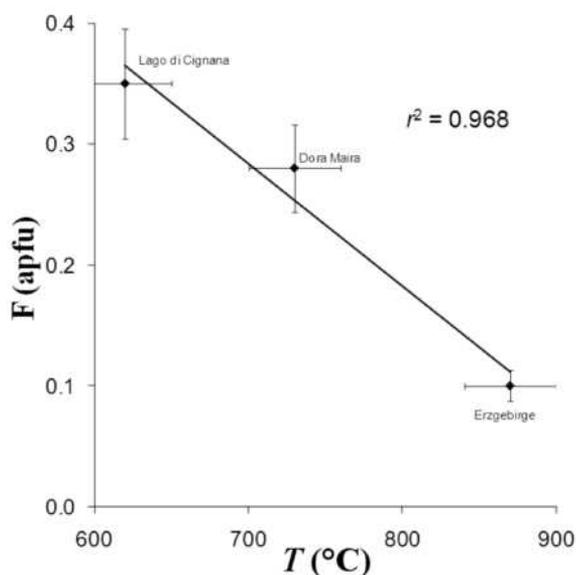

FIGURE 5. Relationship between the F content (Table 4) and the temperature conditions of tourmaline formation. By using the refined F data (Table 2) the correlation coefficient becomes $r^2 = 1.000$. Bars = average estimated standard deviation ($\pm 1\sigma$).

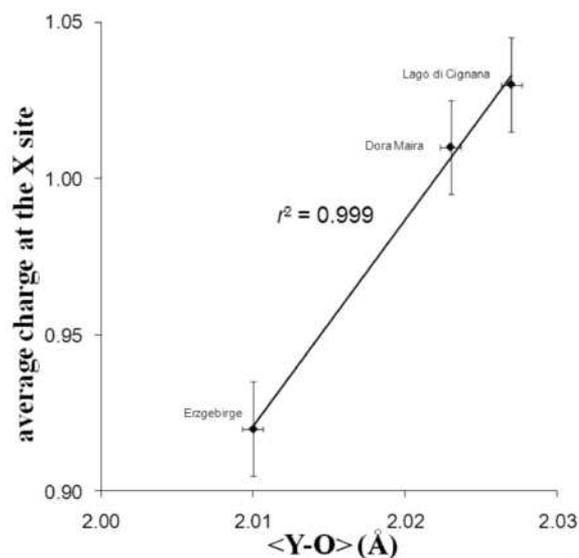

FIGURE 6. Relationship between the average charge at the X site and the $\langle Y-O \rangle$ distance (Table 3). Bars = average estimated standard deviation ($\pm 1\sigma$).

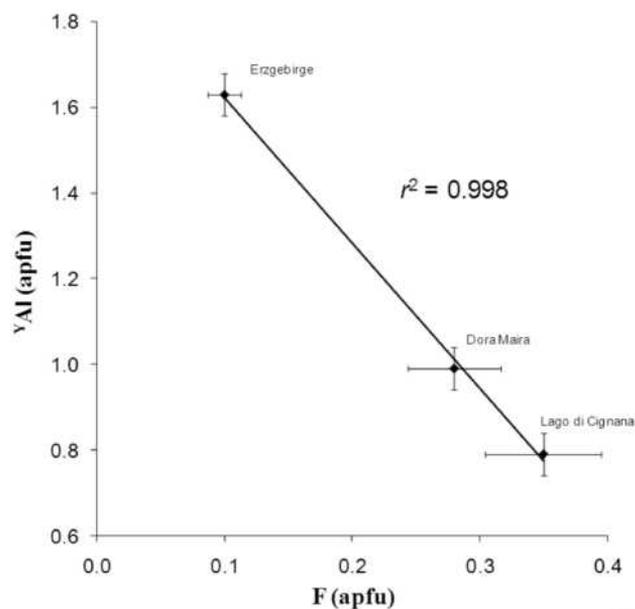

FIGURE 7. Relationship between F content (Table 4) and the Al content of the Y site. Bars = average estimated standard deviation ($\pm 1\sigma$).

$^w[\text{O}_{0.81}\text{F}_{0.10}(\text{OH})_{0.09}]$ is dominated by Al at the Y site.

There is an excellent positive correlation ($r^2 = 0.99$) between the ^{61}Al content (sum of Al at the Y and Z site) of the investigated UHP tourmaline samples and the temperature of tourmaline formation (Figs. 9 and 10). An increase of octahedral Al in the UHP tourmaline samples can be explained via a combination of the (simplified) exchange vectors $^x\Box^{61}\text{AlOH}(\text{NaR}^{2+}\text{F})_{-1}$, $^{61}\text{AlO}(\text{R}^{2+}\text{F})_{-1}$, and $^x\Box^{61}\text{AlOH}(\text{CaR}^{2+}\text{O})_{-1}$ (with $\text{R}^{2+} = \text{Fe}^{2+} + \text{Mn}^{2+} + \text{Mg}$), in which the first vector is a modified version of the exchange vector suggested by Henry and Dutrow (1996),

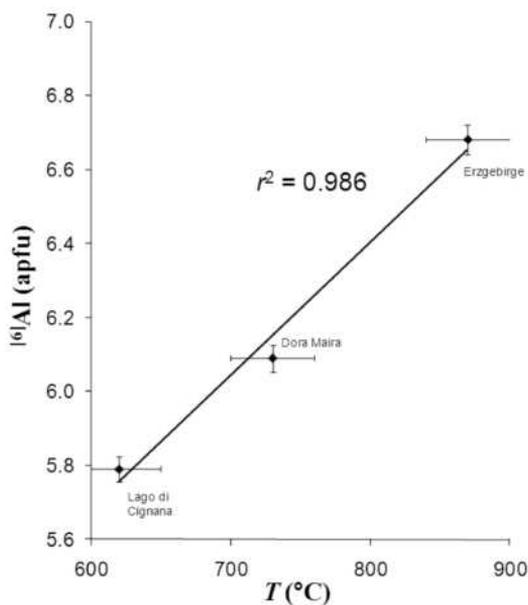

FIGURE 9. Relationship between the ^{61}Al content (sum of Al at the Y- and Z sites) and the temperature conditions of tourmaline formation. Vertical bars = average estimated standard deviation ($\pm 1\sigma$).

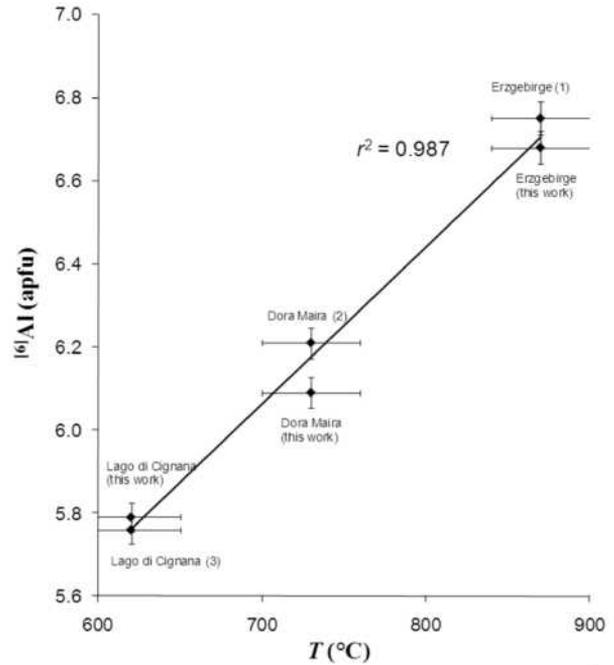

FIGURE 10. Relationship between the temperature conditions of tourmaline formation and the ^{61}Al content (sum of Al at the Y and Z sites). Also plotted are data from samples R6b (1) coesite-bearing mantle of the tourmaline, Erzgebirge, Germany (Marschall et al. 2009), (2) dravite inclusion from a small pyrope crystal from Dora Maira (Schreyer 1985), and (3) a tourmaline from Lago di Cignana, Zermatt-Saas zone, Western Alps (Reinecke 1991). Vertical bars = average estimated standard deviation (1σ).

$^x\Box\text{Al}(\text{NaR}^{2+})_{-1}$, for diagenetic to high-grade metamorphic tourmaline.

Tourmaline crystals from UHP metamorphic conditions are uncommon. Further studies should now focus on the interrelation between the crystal chemistry and metamorphic *P-T* conditions of tourmaline by investigating samples of well-defined metamorphic histories, including high-*P* and diagenetic to high-*T* samples. Consequently, further detailed field, petrographic, and experimental studies undoubtedly would help to solve the problems associated with the tourmaline chemistry (including the occupancy of the Y and Z site) in metamorphic terranes.

ACKNOWLEDGMENTS

Special thanks to Thomas Reinecke, Bochum, Germany, for providing samples of the tourmaline- and piemontite-bearing garnet-phengite-coesite-schist from Lago di Cignana, Western Alps, as well as for the photograph of the euhedral tourmaline crystal with the coesite inclusion, for different references and for helpful discussions. We thank A. Wagner, Vienna, Austria, for preparing the tourmaline samples and Olaf Medenbach for extracting pieces of the tourmaline from a Dora Maira thin section. This work was supported by Österreichischer Fonds zur Förderung der wissenschaftlichen Forschung (FWF) project no. P20509. We sincerely thank Alfonso Pesquera and Carl Francis for their careful reviews of the manuscript.
